FEATURES

12-/10-/8-bit ADCs with fast conversion time: 1 µs typical 4 analog input channels/3 analog input channels with reference input Specified for V_{DD} of 2.7 V to 5.5 V **Sequencer operation Temperature range: −40°C to +125°C I 2C-compatible serial interface supports standard, fast, and high speed modes 2 versions allow 2 I2C addresses Low power consumption Shutdown mode: 1 µA maximum 8-lead SOT-23 package Qualified for automotive applications**

APPLICATIONS

System monitoring Battery-powered systems Data acquisition Medical instruments

GENERAL DESCRIPTION

The AD7991/AD7995/AD7999 are 12-/10-/8-bit, low power, successive approximation ADCs with an I²C[®]-compatible interface. Each part operates from a single 2.7 V to 5.5 V power supply and features a 1 µs conversion time. The track-and-hold amplifier allows each part to handle input frequencies of up to 14 MHz, and a multiplexer allows taking samples from four channels.

Each AD7991/AD7995/AD7999 provides a 2-wire serial interface compatible with I2 C interfaces. The AD7991 and AD7995 come in two versions and each version has an individual I 2 C address. This allows two of the same devices to be connected to the same I²C bus. Both versions support standard, fast, and high speed I²C interface modes. The AD7999 comes in one version.

The AD7991/AD7995/AD7999 normally remain in a shutdown state, powering up only for conversions. The conversion process is controlled by a command mode, during which each I²C read operation initiates a conversion and returns the result over the I 2 C bus.

When four channels are used as analog inputs, the reference for the part is taken from V_{DD} ; this allows the widest dynamic input range to the ADC. Therefore, the analog input range to the

FUNCTIONAL BLOCK DIAGRAM

ADC is 0 V to V_{DD} . An external reference, applied through the V_{IN3}/V_{REF} input, can also be used with this part.

PRODUCT HIGHLIGHTS

- 1. Four single-ended analog input channels, or three singleended analog input channels and one reference input channel.
- $2.$ 2 C-compatible serial interface. Standard, fast, and high speed modes.
- 3. Automatic shutdown.
- 4. Reference derived from the power supply or external reference.
- 5. 8-lead SOT-23 package.

ABSOLUTE MAXIMUM RATINGS

 $T_A = 25$ °C, unless otherwise noted.

Table 6.

¹ Transient currents of up to 100 mA do not cause SCR latch-up.

Stresses at or above those listed under Absolute Maximum Ratings may cause permanent damage to the product. This is a stress rating only; functional operation of the product at these or any other conditions above those indicated in the operational section of this specification is not implied. Operation beyond the maximum operating conditions for extended periods may affect product reliability.

ESD CAUTION

ESD (electrostatic discharge) sensitive device. Charged devices and circuit boards can discharge without detection. Although this product features patented or proprietary protection circuitry, damage may occur on devices subjected to high energy ESD. Therefore, proper ESD precautions should be taken to avoid performance degradation or loss of functionality.

TERMINOLOGY

Signal-to-Noise and Distortion (SINAD) Ratio

The measured ratio of signal-to-noise and distortion at the output of the ADC. The signal is the rms amplitude of the fundamental. Noise is the sum of the nonfundamental signals excluding dc, up to half the sampling frequency $(f_s/2)$. The ratio is dependent on the number of quantization levels in the digitization process: the more levels, the smaller the quantization noise. The theoretical SINAD ratio for an ideal N-bit converter with a sine wave input is given by

 $Signal-to-(Noise + Distribution) = (6.02 N + 1.76) dB$

Therefore, SINAD is 49.92 dB for an 8-bit converter, 61.96 dB for a 10-bit converter, and 74 dB for a 12-bit converter.

Total Harmonic Distortion (THD)

The ratio of the rms sum of harmonics to the fundamental. For the AD7991/AD7995/AD7999, it is defined as

$$
THD (dB) = 20 \log \frac{\sqrt{V_2^2 + V_3^2 + V_4^2 + V_5^2 + V_6^2}}{V_1}
$$

where:

V1 is the rms amplitude of the fundamental. *V2*, *V3*, *V4*, *V5*, and *V6* are the rms amplitudes of the second through sixth harmonics.

Peak Harmonic or Spurious Noise

The ratio of the rms value of the next largest component in the ADC output spectrum (up to $f_s/2$ and excluding dc) to the rms value of the fundamental. Typically, the value of this specification is determined by the largest harmonic in the spectrum, but for ADCs where the harmonics are buried in the noise floor, the largest harmonic may be a noise peak.

Intermodulation Distortion

With inputs consisting of sine waves at two frequencies, fa and fb, any active device with nonlinearities creates distortion products at sum and difference frequencies of mfa \pm nfb, where m, $n = 0, 1, 2, 3$, and so on. Intermodulation distortion terms are those for which neither *m* nor *n* equals 0. For example, second-order terms include $(fa + fb)$ and $(fa - fb)$, and third-order terms include $(2fa + fb)$, $(2fa - fb)$, $(fa + 2fb)$, and $(fa - 2fb)$.

The AD7991/AD7995/AD7999 are tested using the CCIF standard, where two input frequencies near the maximum input bandwidth are used. In this case, the second-order terms are usually distanced

in frequency from the original sine waves, and the third-order terms are usually at a frequency close to the input frequencies. As a result, the second- and third-order terms are specified separately. The calculation of intermodulation distortion is, like the THD specification, the ratio of the rms sum of the individual distortion products to the rms amplitude of the sum of the fundamentals, expressed in decibels.

Channel-to-Channel Isolation

Channel-to-channel isolation is a measure of the level of crosstalk between any two channels. It is measured by applying a full-scale sine wave signal to all unselected input channels and then determining the degree to which the signal attenuates in the selected channel with a 10 kHz signal. The frequency of the signal in each of the unselected channels is increased from 2 kHz up to 92 kHz[. Figure 14](#page-13-0) shows the worst-case across all four channels for the AD7991.

Full-Power Bandwidth

The input frequency at which the amplitude of the reconstructed fundamental is reduced by 0.1 dB or 3 dB for a full-scale input.

Integral Nonlinearity

The maximum deviation from a straight line passing through the endpoints of the ADC transfer function. The endpoints are at zero scale (a point 1 LSB below the first code transition) and full scale (a point 1 LSB above the last code transition).

Differential Nonlinearity

The difference between the measured and the ideal 1 LSB change between any two adjacent codes in the ADC.

Offset Error

The deviation of the first code transition (00 … 000 to $00 \ldots 001$) from the ideal—that is, AGND + 1 LSB.

Offset Error Match

The difference in offset error between any two channels.

Gain Error

The deviation of the last code transition (111 … 110 to 111 ... 111) from the ideal (that is, V_{REF} – 1 LSB) after the offset error has been adjusted out.

Gain Error Match

The difference in gain error between any two channels.

THEORY OF OPERATION

The AD7991/AD7995/AD7999 are low power, 12-/10-/8-bit, single-supply, 4-channel ADCs. Each part can be operated from a single 2.35 V to 5.5 V supply.

The AD7991/AD7995/AD7999 provide the user with a 4-channel multiplexer, an on-chip track-and-hold, an ADC, and an I²Ccompatible serial interface, all housed in an 8-lead SOT-23 package that offers the user considerable space-saving advantages over alternative solutions.

The AD7991/AD7995/AD7999 normally remains in a powerdown state while not converting. Therefore, when supplies are first applied, the part is in a power-down state. Power-up is initiated prior to a conversion, and the device returns to the power-down state upon completion of the conversion. This automatic powerdown feature allows the device to save power between conversions. This means any read or write operations across the $I²C$ interface can occur while the device is in power-down.

CONVERTER OPERATION

The AD7991/AD7995/AD7999 are successive approximation ADCs built around a capacitive DAC[. Figure 18](#page-16-2) an[d Figure 19](#page-16-3) show simplified schematics of the ADC during its acquisition and conversion phases, respectively[. Figure 18 s](#page-16-2)hows the ADC during its acquisition phase: SW2 is closed, SW1 is in Position A, the comparator is held in a balanced condition, and the sampling capacitor acquires the signal on V_{IN} . The source driving the analog input needs to settle the analog input signal to within one LSB in 0.6 μs, which is equivalent to the duration of the power-up and acquisition time.

When the ADC starts a conversion, as shown i[n Figure 19,](#page-16-3) SW2 opens and SW1 moves to Position B, causing the comparator to become unbalanced. The input is disconnected when the conversion begins. The control logic and the capacitive DAC are used to add and subtract fixed amounts of charge from the sampling capacitor to bring the comparator back into a balanced condition. When the comparator is rebalanced, the conversion is complete. The control logic generates the ADC output code[. Figure 20 s](#page-16-4)hows the ADC transfer function.

ADC Transfer Function

The output coding of the AD7991/AD7995/AD7999 is straight binary. The designed code transitions occur at successive integer LSB values (that is, 1 LSB, 2 LSB, and so on). The LSB size for the AD7991/AD7995/AD7999 is VREF/4096, VREF/1024, and VREF/256, respectively[. Figure 20](#page-16-4) shows the ideal transfer characteristics for the AD7991/AD7995/AD7999.

Figure 20. AD7991/AD7995/AD7999 Transfer Characteristics

TYPICAL CONNECTION DIAGRAM

[Figure 22 s](#page-17-2)hows the typical connection diagram for the AD7991/AD7995/AD7999.

The reference voltage can be taken from the supply voltage, V_{DD}. However, the AD7991/AD7995/AD7999 can be configured to be a 3-channel device with the reference voltage applied to the V_{IN3}/V_{REF} pin. In this case, a 1 μ F decoupling capacitor on the V_{IN3}/V_{REF} pin is recommended.

SDA and SCL form the 2-wire I²C compatible interface. External pull-up resistors are required for both the SDA and SCL lines.

The AD7991-0/AD7995-0 and the AD7991-1/AD7995-1/ AD7999-1 support standard, fast, and high speed $I²C$ interface modes. Both the -0 and -1 devices have independent I²C addresses, which allows the devices to connect to the same I²C bus without contention issues.

The part requires approximately 0.6 μs to wake up from powerdown and to acquire the analog input. Once the acquisition phase ends, the conversion phase starts and takes approximately 1 μs to complete. The AD7991/AD7995/AD7999 enters shutdown mode after each conversion, which is useful in applications where power consumption is a concern.

ANALOG INPUT

[Figure 21 s](#page-17-3)hows an equivalent circuit of the AD7991/AD7995/ AD7999 analog input structure. The two diodes, D1 and D2, provide ESD protection for the analog inputs. Care must be taken to ensure that the analog input signal does not exceed the supply rails by more than 300 mV. If the signal does exceed this level, the diodes become forward-biased and start conducting current into the substrate. Each diode can conduct a maximum current of 10 mA without causing irreversible damage to the part.

Figure 21. Equivalent Analog Input Circuit

Capacitor C1 in [Figure 21 i](#page-17-3)s typically about 4 pF and can primarily be attributed to pin capacitance. Resistor R1 is a lumped component composed of the on resistance (RON) of both a track-and-hold switch and the input multiplexer. The total resistor is typically about 400 Ω. Capacitor C2, the ADC sampling capacitor, has a typical capacitance of 30 pF.

Figure 22. AD7991/AD7995/AD7999 Typical Connection Diagram

Data Sheet Advertised [AD7991](http://www.analog.com/AD7991?doc=AD7991_7995_7999.pdf)[/AD7995](http://www.analog.com/AD7995?doc=AD7991_7995_7999.pdf)[/AD7999](http://www.analog.com/AD7999?doc=AD7991_7995_7999.pdf)99999

For ac applications, removing high frequency components from the analog input signal is recommended by use of an RC bandpass filter on the relevant analog input pin. In applications where harmonic distortion and signal-to-noise ratio are critical, the analog input should be driven from a low impedance source. Large source impedances significantly affect the ac performance of the ADC. This may necessitate the use of an input buffer amplifier. The choice of the op amp is a function of the particular application.

When no amplifier is used to drive the analog input, the source impedance should be limited to low values. The maximum source impedance depends on the amount of THD that can be tolerated. THD increases as the source impedance increases and performance degrades. [Figure 23](#page-18-0) shows the THD vs. the analog input signal frequency for different source impedances at a supply voltage of 5 V.

ANALOG INPUT FREQUENCY (kHz)

INTERNAL REGISTER STRUCTURE

CONFIGURATION REGISTER

The configuration register is an 8-bit write-only register that is used to set the operating modes of the AD7991/AD7995/AD7999. The bit functions are outlined in [Table 10.](#page-19-2) A single-byte write is necessary when writing to the configuration register. D7 is the MSB. When the master writes to the AD7991/AD7995/AD7999, the first byte is written to the configuration register.

Table 9. Configuration Register Bit Map and Default Settings at Power-Up

Table 11. Channel Selection

¹ The AD7991/AD7995/AD7999 converts on the selected channel in the sequence in ascending order, starting with the lowest channel in the sequence.

SAMPLE DELAY AND BIT TRIAL DELAY

It is recommended that no I²C bus activity occur while a conversion is taking place (see [Figure 27](#page-24-1) and the [Placing the](#page-24-0) [AD7991/AD7995/AD7999](#page-24-0) into High Speed Mode section). However, if this is not always possible, then in order to maintain the performance of the ADC, Bits D0 and D1 in the configuration register are used to delay critical sample intervals and bit trials from occurring while there is activity on the I²C bus. This results in a quiet period for each bit decision. However, the sample delay protection may introduce excessive jitter, degrading the SNR for large signals above 300 Hz. For guaranteed ac performance, use of clock stretching is recommended.

When Bit D0 and Bit D1 are both 0, the bit trial and sample interval delay mechanism is implemented. The default setting of D0 and D1 is 0. To turn off both delay mechanisms, set D0 and D1 to 1.

CONVERSION RESULT REGISTER

The conversion result register is a 16-bit read-only register that stores the conversion result from the ADC in straight binary format. A 2-byte read is necessary to read data from this register. [Table 12](#page-20-2) shows the contents of the first byte to be read from AD7991/AD7995/AD7999, an[d Table 13](#page-20-3) shows the contents of the second byte to be read.

Each AD7991/AD7995/AD7999 conversion result consists of two leading 0s, two channel identifier bits, and the 12-/10-/8-bit data result. For the AD7995, the two LSBs (D1 and D0) of the second read contain two trailing 0s. For the AD7999, the four LSBs (D3, D2, D1, and D0) of the second read contain four trailing 0s.

Table 12. Conversion Value Register (First Read)

Table 13. Conversion Value Register (Second Read)

SERIAL INTERFACE

Control of the AD7991/AD7995/AD7999 is accomplished via the I²C-compatible serial bus. The AD7991/AD7995/AD7999 is connected to this bus as a slave device under the control of a master device, such as the processor.

SERIAL BUS ADDRESS

Like all I²C-compatible devices, the AD7991/AD7995/AD7999 has a 7-bit serial address. The devices are available in two versions, the AD7991-0/AD7995-0 and the AD7991-1/AD7995-1/AD7999-1. Each version has a different address(se[e Table 8\)](#page-11-1), which allows up to two AD7991/AD7995 devices to be connected to a single serial bus. AD7999 has only one version.

The serial bus protocol operates as follows:

- 1. The master initiates a data transfer by establishing a start condition, defined as a high-to-low transition on the serial data line SDA while the serial clock line, SCL, remains high. This indicates that an address/data stream follows.
- 2. All slave peripherals connected to the serial bus respond to the start condition and shift in the next eight bits, consisting of a 7-bit address (MSB first) plus an R/\overline{W} bit that determines the direction of the data transfer—that is, whether data is written to or read from the slave device.
- 3. The peripheral whose address corresponds to the transmitted address responds by pulling the data line low during the low period before the ninth clock pulse, known as the acknowledge bit. All other devices on the bus remain idle while the selected device waits for data to be read from or written to it. If the R/\overline{W} bit is set to 0, the master writes to the slave device. If the R/\overline{W} bit is set to 1, the master reads from the slave device.
- 4. Data is sent over the serial bus in sequences of nine clock pulses—eight bits of data followed by an acknowledge bit from the receiver of data. Transitions on the data line must occur during the low period of the clock signal and remain stable during the high period because a low-to-high transition when the clock is high may be interpreted as a stop signal.
- 5. When all data bytes have been read or written, stop conditions are established. In write mode, the master pulls the data line high during the $10th$ clock pulse to assert a stop condition. In read mode, the master device pulls the data line high during the low period before the ninth clock pulse. This is known as a no acknowledge. The master takes the data line low during the low period before the 10th clock pulse, and then high during the 10th clock pulse to assert a stop condition.
- 6. Any number of bytes of data can be transferred over the serial bus in one operation, but it is not possible to mix reads and writes in one operation because the type of operation is determined at the beginning and cannot subsequently be changed without starting a new operation.

WRITING TO THE AD7991/AD7995/AD7999

By default, each part operates in read-only mode and all four channels are selected as enabled in the configuration register. To write to the AD7991/AD7995/AD7999 configuration register, the user must first address the device.

The configuration register is an 8-bit register; therefore, only one byte of data can be written to this register. However, writing a single byte of data to this register consists of writing the serial bus write address, followed by the data byte written (se[e Figure 24\)](#page-22-1).

READING FROM THE AD7991/AD7995/AD7999

Reading data from the conversion result register is a 2-byte operation, as shown in [Figure 25.](#page-23-1) Therefore, a read operation always involves two bytes.

After the AD7991/AD7995/AD7999 have received a read address, any number of reads can be performed from the conversion result register.

Following a start condition, the master writes the 7-bit address of the AD7991/AD7995/AD7999 and then sets R/\overline{W} to 1. The AD7991/AD7995/AD7999 acknowledge this by pulling the SDA line low. They then output the conversion result over the I 2 C bus, preceded by four status bits. The status bits are two leading 0s followed by the channel identifier bits. For the AD7995 there are two trailing 0s, and for the AD7999 there are four trailing 0s.

After the master has addressed the AD7991/AD7995/AD7999, the part begins to power up on the ninth SCLK rising edge. At the same time, the acquisition phase begins. When approximately 0.6 µs have elapsed, the acquisition phase ends. The input is sampled and a conversion begins. This is done in parallel to the

read operation and should not affect the read operation. The master reads back two bytes of data. On the ninth SCLK rising edge of the second byte, if the master sends an ACK, it keeps reading conversion results and the AD7991/AD7995/AD7999 powers up and performs a second conversion. If the master sends a NO ACK, the AD7991/AD7995/AD7999 does not power up on the ninth SCLK rising edge of the second byte. If a further conversion is required, the part converts on the next channel, as selected in the configuration register. Se[e Table 11](#page-19-3) for information about the channel selection.

If the master sends a NO ACK on the ninth SCLK rising edge of the second byte, the conversion is finished and no further conversion is performed.

To put the part into full shutdown mode, the user should issue a stop condition to the AD7991/AD7995/AD7999. If the AD7991/ AD7995/AD7999 is not put into full shutdown mode, it will draw a few tens of microamperes from the supply.

Figure 25. Reading Two Bytes of Data from the AD7991Conversion Result Register

PLACING THE AD7991/AD7995/AD7999 INTO HIGH SPEED MODE

High speed mode communication commences after the master addresses all devices connected to the bus with the master code, 00001XXX, to indicate that a high speed mode transfer is to begin. No device connected to the bus is allowed to acknowledge the high speed master code; therefore, the code is followed by a NO ACK (se[e Figure 26\)](#page-24-2). The master must then issue a repeated start, followed by the device address and an R/\overline{W} bit. The selected device then acknowledges its address.

All devices continue to operate in high speed mode until the master issues a stop condition. When the stop condition is issued, the devices return to fast mode.

To guarantee performance above $f_{SCL} = 1.7$ MHz, the user must perform clock stretching—that is, the clock must be held high—for 2 μs after the ninth clock rising edge (se[e Figure 27\)](#page-24-1). Therefore, the clock must be held high for 2 μs after the device starts to power up (see th[e Reading from the AD7991/AD7995/AD7999 s](#page-23-0)ection).

Figure 27. Reading Two Bytes of Data from the Conversion Result Register in High Speed Mode for AD7991

MODE OF OPERATION

The AD7991/AD7995/AD7999 powers up in shutdown mode. After the master addresses the AD7991/AD7995/AD7999 with the correct I2 C address, the ADC acknowledges the address. In response, the AD7991/AD7995/AD7999 power up.

During this wake up time, the AD7991/AD7995/AD7999 exit shutdown mode and begin to acquire the analog input (acquisition phase). By default, all channels are selected. Which channels are converted depends on the status of the channel bits in the configuration register.

When the read address is acknowledged, the ADC outputs two bytes of conversion data. The first byte contains four status bits and the four MSBs of the conversion result. The status bits contain two leading 0s and two channel-identifier bits. After this first byte, the AD7991/AD7995/AD7999 outputs the

second byte of the conversion result. For the AD7991, this second byte contains the lower eight bits of conversion data. For the AD7995, this second byte contains six bits of conversion data plus two trailing 0s. For the AD7999, this second byte contains four bits of conversion data and four trailing 0s.

The master then sends a NO ACK to the AD7991/AD7995/ AD7999, as long as no further reads are required. If the master instead sends an ACK to the AD7991/AD7995/AD7999, the ADC powers up and completes another conversion. When more than one channel bit has been set in the configuration register, this conversion is performed on the second channel in the selected sequence. If only one channel is selected, the ADC converts again on the selected channel.
