## FAN3223/FAN3224/FAN3225

### Description

The FAN3223–25 family of dual 4 A gate drivers is designed to drive N-channel enhancement-mode MOSFETs in low-side switching applications by providing high peak current pulses during the short switching intervals. The driver is available with either TTL or CMOS input thresholds. Internal circuitry provides an under-voltage lockout function by holding the output LOW until the supply voltage is within the operating range. In addition, the drivers feature matched internal propagation delays between A and B channels for applications requiring dual gate drives with critical timing, such as synchronous rectifiers. This also enables connecting two drivers in parallel to effectively double the current capability driving a single MOSFET.

The FAN322X drivers incorporate MillerDrive™ architecture for the final output stage. This bipolar–MOSFET combination provides high current during the Miller plateau stage of the MOSFET turn-on / turn-off process to minimize switching loss, while providing rail-to-rail voltage swing and reverse current capability.

The FAN3223 offers two inverting drivers and the FAN3224 offers two non-inverting drivers. Each device has dual independent enable pins that default to ON if not connected. In the FAN3225, each channel has dual inputs of opposite polarity, which allows configuration as non-inverting or inverting with an optional enable function using the second input. If one or both inputs are left unconnected, internal resistors bias the inputs such that the output is pulled LOW to hold the power MOSFET OFF.

14. The initial spike in each current waveform is a measurement artifact caused by the stray inductance of the current-measurement loop.

### APPLICATIONS INFORMATION

#### Input Thresholds

Each member of the FAN322x driver family consists of two identical channels that may be used independently at rated current or connected in parallel to double the individual current capacity. In the FAN3223 and FAN3224, channels A and B can be enabled or disabled independently using ENA or ENB, respectively. The EN pin has TTL thresholds for parts with either CMOS or TTL input thresholds. If ENA and ENB are not connected, an internal pull-up resistor enables the driver channels by default. ENA and ENB have TTL thresholds in parts with either TTL or CMOS  $IN_x$  threshold.

If the channel A and channel B inputs and outputs are connected in parallel to increase the driver current capacity, ENA and ENB should be connected and driven together. In addition, it is recommended to include an individual gate resistance for each channel output to limit the shoot through current possibly happening between the two channels due to variations in propagation delay or in input threshold between the two channels.

The FAN322x family offers versions in either TTL or CMOS input thresholds. In the FAN322xT, the input thresholds meet industry-standard TTL-logic thresholds independent of the  $V_{DD}$  voltage, and there is a hysteresis voltage of approximately 0.4 V. These levels permit the inputs to be driven from a range of input logic signal levels for which a voltage over 2 V is considered logic HIGH. The driving signal for the TTL inputs should have fast rising and falling edges with a slew rate of 6 V/ $\mu$ s or faster, so a rise time from 0 to 3.3 V should be 550 ns or less. With reduced

slew rate, circuit noise could cause the driver input voltage to exceed the hysteresis voltage and retrigger the driver input, causing erratic operation.

In the FAN322xC, the logic input thresholds are dependent on the  $V_{DD}$  level and, with  $V_{DD}$  of 12 V, the logic rising edge threshold is approximately 55% of  $V_{DD}$  and the input falling edge threshold is approximately 38% of  $V_{DD}$ . The CMOS input configuration offers a hysteresis voltage of approximately 17% of  $V_{DD}$ . The CMOS inputs can be used with relatively slow edges (approaching DC) if good decoupling and bypass techniques are incorporated in the system design to prevent noise from violating the input voltage hysteresis window. This allows setting precise timing intervals by fitting an R-C circuit between the controlling signal and the IN pin of the driver. The slow rising edge at the IN pin of the driver introduces a delay between the controlling signal and the OUT pin of the driver.

#### Static Supply Current

In the  $I_{DD}$  (static) typical performance characteristics (Figure 11 – Figure 13 and Figure 18 – Figure 20), the curve is produced with all inputs/enables floating (OUT is low) and indicates the lowest static  $I_{DD}$  current for the tested configuration. For other states, additional current flows through the 100 k $\Omega$  resistors on the inputs and outputs shown in the block diagram of each part (see Figure 4 – Figure 6). In these cases, the actual static  $I_{DD}$  current is the value obtained from the curves plus this additional current.

### MillerDrive Gate Drive Technology

FAN322x gate drivers incorporate the MillerDrive architecture shown in Figure 46. For the output stage, a combination of bipolar and MOS devices provide large currents over a wide range of supply voltage and temperature variations. The bipolar devices carry the bulk of the current as OUT swings between 1/3 to 2/3  $V_{DD}$  and the MOS devices pull the output to the HIGH or LOW rail.

The purpose of the MillerDrive architecture is to speed up switching by providing high current during the Miller plateau region when the gate–drain capacitance of the MOSFET is being charged or discharged as part of the turn–on / turn–off process.

For applications that have zero voltage switching during the MOSFET turn–on or turn–off interval, the driver supplies high peak current for fast switching even though the Miller plateau is not present. This situation often occurs in synchronous rectifier applications because the body diode is generally conducting before the MOSFET is switched ON.

The output pin slew rate is determined by  $V_{DD}$  voltage and the load on the output. It is not user adjustable, but a series resistor can be added if a slower rise or fall time at the MOSFET gate is needed.

Figure 46. MillerDrive Output Architecture

### Under–Voltage Lockout

The FAN322x startup logic is optimized to drive ground–referenced N–channel MOSFETs with an under–voltage lockout (UVLO) function to ensure that the IC starts up in an orderly fashion. When  $V_{DD}$  is rising, yet below the UVLO level, this circuit holds the output LOW, regardless of the status of the input pins. After the part is active, the supply voltage must drop 0.2 V before the part shuts down. This hysteresis helps prevent chatter when low  $V_{DD}$  supply voltages have noise from the power switching. This configuration is not suitable for driving high–side P–channel MOSFETs because the low output voltage of the driver would turn the P–channel MOSFET ON with  $V_{DD}$  below the UVLO level.

### $V_{DD}$ Bypass Capacitor Guidelines

To enable this IC to turn a device ON quickly, a local high–frequency bypass capacitor,  $C_{BYP}$ , with low ESR and ESL should be connected between the  $V_{DD}$  and GND pins with minimal trace length. This capacitor is in addition to the bulk electrolytic capacitance of 10  $\mu$ F to 47  $\mu$ F commonly found on the driver and controller bias circuits.

A typical criterion for choosing the value of  $C_{BYP}$  is to keep the ripple voltage on the  $V_{DD}$  supply to  $\leq 5\%$ . This is often achieved with a value  $\geq 20$  times the equivalent load capacitance  $C_{EQV}$ , defined here as  $Q_{GATE}/V_{DD}$ . Ceramic capacitors of 0.1  $\mu$ F to 1  $\mu$ F or larger are common choices, as are dielectrics, such as X5R and X7R with good temperature characteristics and high pulse current capability.

If circuit noise affects normal operation, the value of  $C_{BYP}$  may be increased to 50–100 times the  $C_{EQV}$ , or  $C_{BYP}$  may be split into two capacitors. One should be a larger value, based on equivalent load capacitance, and the other a smaller value, such as 1–10 nF mounted closest to the  $V_{DD}$  and GND pins to carry the higher frequency components of the current pulses. The bypass capacitor must provide the pulsed current from both of the driver channels and, if the drivers are switching simultaneously, the combined peak current sourced from the  $C_{BYP}$  would be twice as large as when a single channel is switching.

### Layout and Connection Guidelines

The FAN3223–25 family of gate drivers incorporates fast–reacting input circuits, short propagation delays, and powerful output stages capable of delivering current peaks over 4 A to facilitate voltage transition times from under 10 ns to over 150 ns. The following layout and connection guidelines are strongly recommended:

- Keep high–current output and power ground paths separate logic and enable input signals and signal ground paths. This is especially critical when dealing with TTL–level logic thresholds at driver inputs and enable pins
- Keep the driver as close to the load as possible to minimize the length of high–current traces. This reduces the series inductance to improve high–speed switching, while reducing the loop area that can radiate EMI to the driver inputs and surrounding circuitry
- If the inputs to a channel are not externally connected, the internal 100 k $\Omega$  resistors indicated on block diagrams command a low output. In noisy environments, it may be necessary to tie inputs of an unused channel to  $V_{DD}$  or GND using short traces to prevent noise from causing spurious output switching

- Many high-speed power circuits can be susceptible to noise injected from their own output or other external sources, possibly causing output re-triggering. These effects can be obvious if the circuit is tested in breadboard or non-optimal circuit layouts with long input, enable, or output leads. For best results, make connections to all pins as short and direct as possible
- The FAN322x is compatible with many other industry-standard drivers. In single input parts with enable pins, there is an internal 100 kΩ resistor tied to VDD to enable the driver by default; this should be considered in the PCB layout
- The turn-on and turn-off current paths should be minimized, as discussed in the following section

Figure 47 shows the pulsed gate drive current path when the gate driver is supplying gate charge to turn the MOSFET ON. The current is supplied from the local bypass capacitor, C<sub>BYP</sub>, and flows through the driver to the MOSFET gate and to ground. To reach the high peak currents possible, the resistance and inductance in the path should be minimized. The localized C<sub>BYP</sub> acts to contain the high peak current pulses within this driver-MOSFET circuit, preventing them from disturbing the sensitive analog circuitry in the PWM controller.

Figure 47. Current Path for MOSFET Turn-On

Figure 48 shows the current path when the gate driver turns the MOSFET OFF. Ideally, the driver shunts the current directly to the source of the MOSFET in a small circuit loop. For fast turn-off times, the resistance and inductance in this path should be minimized.

Figure 48. Current Path for MOSFET Turn-Off

**Truth Table of Logic Operation**

The FAN3225 truth table indicates the operational states using the dual-input configuration. In a non-inverting driver configuration, the IN- pin should be a logic LOW signal. If the IN- pin is connected to logic HIGH, a disable function is realized, and the driver output remains LOW regardless of the state of the IN+ pin.

IN+	IN-	OUT
0	0	0
0	1	0
1	0	1
1	1	0

In the non-inverting driver configuration in Figure 49, the IN- pin is tied to ground and the input signal (PWM) is applied to IN+ pin. The IN- pin can be connected to logic HIGH to disable the driver and the output remains LOW, regardless of the state of the IN+ pin.

Figure 49. Dual-Input Driver Enabled, Non-Inverting Configuration

In the inverting driver application in Figure 50, the IN+ pin is tied HIGH. Pulling the IN+ pin to GND forces the output LOW, regardless of the state of the IN- pin.

Figure 50. Dual-Input Driver Enabled, Inverting Configuration

**Operational Waveforms**

At power-up, the driver output remains LOW until the V<sub>DD</sub> voltage reaches the turn-on threshold. The magnitude of the OUT pulses rises with V<sub>DD</sub> until steady-state V<sub>DD</sub> is reached. The non-inverting operation illustrated in Figure 51 shows that the output remains LOW until the UVLO threshold is reached, then the output is in-phase with the input.

Figure 51. Non-Inverting Startup Waveforms

For the inverting configuration of Figure 50, startup waveforms are shown in Figure 52. With IN+ tied to VDD and the input signal applied to IN-, the OUT pulses are inverted with respect to the input. At power-up, the inverted output remains LOW until the V<sub>DD</sub> voltage reaches the turn-on threshold, then it follows the input with inverted phase.

**Thermal Guidelines**

Gate drivers used to switch MOSFETs and IGBTs at high frequencies can dissipate significant amounts of power. It is important to determine the driver power dissipation and the resulting junction temperature in the application to ensure that the part is operating within acceptable temperature limits.

The total power dissipation in a gate driver is the sum of two components, P<sub>GATE</sub> and P<sub>DYNAMIC</sub>:

$$P_{TOTAL} = P_{GATE} + P_{DYNAMIC} \quad (eq. 1)$$

P<sub>GATE</sub> (Gate Driving Loss): The most significant power loss results from supplying gate current (charge per unit time) to switch the load MOSFET on and off at the switching frequency. The power dissipation that results from driving a MOSFET at a specified gate-source voltage, V<sub>GS</sub>, with gate charge, Q<sub>G</sub>, at switching frequency, f<sub>SW</sub>, is determined by:

$$P_{GATE} = Q_G \times V_{GS} \times f_{SW} \times n \quad (eq. 2)$$

where n is the number of driver channels in use (1 or 2).

P<sub>DYNAMIC</sub> (Dynamic Pre-Drive / Shoot-through Current): A power loss resulting from internal current consumption under dynamic operating conditions, including pin pull-up / pull-down resistors. The internal current consumption (I<sub>DYNAMIC</sub>) can be estimated using the graphs in Figure 14 and Figure 15 of the Typical Performance Characteristics to determine the current I<sub>DYNAMIC</sub> drawn from V<sub>DD</sub> under actual operating conditions:

$$P_{DYNAMIC} = I_{DYNAMIC} \times V_{DD} \times n \quad (eq. 3)$$

where n is the number of driver ICs in use. Note that n is usually be one IC even if the IC has two channels, unless two or more driver ICs are in parallel to drive a large load.

Once the power dissipated in the driver is determined, the driver junction rise with respect to circuit board can be evaluated using the following thermal equation, assuming  $\Psi_{JB}$  was determined for a similar thermal design (heat sinking and air flow):

$$T_J = P_{TOTAL} \times \Psi_{JB} + T_B \quad (\text{eq. 4})$$

where:

$T_J$  = driver junction temperature;

$\Psi_{JB}$  = (psi) thermal characterization parameter relating temperature rise to total power dissipation; and

$T_B$  = board temperature in location as defined in the Thermal Characteristics table.

To give a numerical example, assume for a 12 V  $V_{DD}$  ( $V_{BIAS}$ ) system, the synchronous rectifier switches of Figure 56 have a total gate charge of 60 nC at  $V_{GS} = 7$  V. Therefore, two devices in parallel would have 120 nC gate charge. At a switching frequency of 300 kHz, the total power dissipation is:

$$P_{GATE} = 120\text{nC} \times 7\text{ V} \times 300\text{ kHz} \times 2 = 0.504\text{ W} \quad (\text{eq. 5})$$

$$P_{DYNAMIC} = 3.0\text{ mA} \times 12\text{ V} \times 1 = 0.036\text{ W} \quad (\text{eq. 6})$$

$$P_{TOTAL} = 0.540\text{ W} \quad (\text{eq. 7})$$

The SOIC-8 has a junction-to-board thermal characterization parameter of  $\Psi_{JB} = 42^\circ\text{C}/\text{W}$ . In a system application, the localized temperature around the device is a function of the layout and construction of the PCB along with airflow across the surfaces. To ensure reliable operation, the maximum junction temperature of the device must be prevented from exceeding the maximum rating of  $150^\circ\text{C}$ ; with 80% derating,  $T_J$  would be limited to  $120^\circ\text{C}$ . Rearranging Equation 4 determines the board temperature required to maintain the junction temperature below  $120^\circ\text{C}$ :

$$T_{B, MAX} = T_J - P_{TOTAL} \times \Psi_{JB} \quad (\text{eq. 8})$$

$$T_{B, MAX} = 120^\circ\text{C} - 0.54\text{ W} \times 42^\circ\text{C}/\text{W} = 97^\circ\text{C} \quad (\text{eq. 9})$$
