## *General Description*

The MAX8553 is a 4.5V to 28V input-voltage, synchronous step-down controller that provides a complete power-management solution for DDR memory. The MAX8553 generates 1/2 VREFIN voltage for VTT and VTTR. The VTT and VTTR tracking voltages are maintained within 1% of 1/2 VREFIN. The MAX8554 is a 4.5V to 28V input voltage, nontracking step-down controller with a low 0.6V feedback threshold voltage. The MAX8553/ MAX8554 use Maxim's proprietary Quick-PWM™ architecture for fast transient response and operate with selectable pseudo-fixed frequencies. Both controllers can operate without an external bias supply.

The controllers operate in synchronous-rectification mode to ensure balanced current sourcing and sinking capability of up to 25A. The MAX8553/MAX8554 also provide up to 95% efficiency, making them ideal for server and pointof-load applications. Additionally, a low 5µA shutdown current allows for longer battery life in notebook applications. Lossless current monitoring is achieved by monitoring the low-side MOSFET's drain-to-source voltage. The MAX8553/MAX8554 have an adjustable foldback current limit to withstand a continuous output overload and short circuit. Digital soft-start provides control of inrush current during power-up. Overvoltage protection shuts the converter down and discharges the output capacitor. The MAX8553/MAX8554 come in space-saving 16-pin QSOP packages.

## *Ordering Information*

### *Features*

- ♦ **Up to 25A Output-Current Capability**
- ♦ **Quick-PWM Control for Fast Loop Response**

**MAXM** 

- ♦ **Up to 95% Efficiency**
- ♦ **4.5V to 28V Input Voltage Range**
- ♦ **No External Bias Supply Required**
- ♦ **0 to 3.6V Input REFIN Range (MAX8553)**
- ♦ **Automatically Sets VTT and VTTR to within** ±**1% of 1/2 VREFIN- (MAX8553)**
- ♦ **Low 0.6V Feedback Threshold (MAX8554)**
- ♦ **200kHz/300kHz/400kHz/550kHz Selectable Switching Frequencies**
- ♦ **Adjustable Foldback Current Limit**
- ♦ **Overvoltage Protection**
- ♦ **Digital Soft-Start**

*Pin Configurations appear at end of data sheet.*

## *Detailed Description*

#### *Internal Linear Regulator*

An internal regulator produces the +5V supply (VL) that powers the PWM controller, MOSFET driver, logic, reference, and other blocks within the IC. This +5V lowdropout (LDO) linear regulator supplies up to 35mA for MOSFET gate-drive and external loads. For supply voltages between +4.5V and +5.5V, connect VL to V+. This bypasses the VL regulator, which improves efficiency and allows the IC to function at lower input voltages.

#### *On-Time One-Shot and Switching Frequency*

The heart of the PWM is the one-shot that sets the highside switch on-time. This fast, low-jitter, adjustable oneshot includes circuitry that varies the on-time in response to both input and output voltages. The highside switch on-time is inversely proportional to the input voltage as measured by the EN/HSD (HSD for the MAX8554) input, and is directly proportional to the output voltage. This algorithm results in a nearly constant switching frequency despite the lack of a fixed-frequency clock generator. The switching frequency can be selected to avoid noise-sensitive regions such as

the 455kHz IF band. Also, with a constant switching frequency, the inductor ripple-current operating point remains relatively constant, resulting in easy design methodology and predictable output voltage ripple. The general formula for the MAX8553 on-time  $(t_{ON})$  is:

$$
t_{ON} = K \times N \times \frac{1}{V_{EN/HSD}} \times V_{OUT}
$$

where  $V_{EN/HSD}$  and  $V_{OUT}$  are the voltages measured at EN/HSD and the output, respectively, and  $K = 1.7 \mu s$ . The value of N depends on the configuration of FSEL and is listed in Table 1.

For the MAX8554, the general formula for on-time  $(t_{ON})$  is:

$$
t_{ON} = K \times N \times \frac{1}{V_{HSD}} \times V_{OUT}
$$

where VHSD and VOUT are the voltages measured at HSD and the output, respectively, and  $K = 1.7 \mu s$ . The value of N depends on the configuration of FSEL and is listed in Table 2.

#### **MAXM**

*MAX8553/MAX8554*

## **Table 1. Configuration of FSEL (MAX8553)**

## **Table 2. Configuration of FSEL (MAX8554)**

This algorithm results in a nearly constant switching frequency despite the lack of a fixed-frequency clock generator. The actual switching frequency, which is given by the following equation, varies slightly due to the voltage drop across the on-resistance of the MOSFETs and the DC resistance of the output inductor:

$$
f_S = \frac{D}{t_{ON}} \cong \frac{1}{K \times N}
$$

where D is the duty cycle:

$$
D = \frac{V_{OUT} + I_0(P_{DSONL} + P_{DC})}{V_{HSD} + I_0(P_{DSONL} - P_{DSONH})}
$$

where Io is the output current, RDSONL is the on-resistance of the low-side MOSFET,  $R_{DSONH}$  is the on-resistance of the high-side MOSFET, and R<sub>DC</sub> is the DC resistance of the output inductor. The ideal switching frequency for VREFIN = 2.5V is about 550kHz. Switching frequency increases for positive (sourcing) load current and decreases for negative (sinking) load current, due to the changing voltage drop across the low-side MOSFET, which changes the inductor-current discharge ramp rate. The on-times guaranteed in the *Electrical Characteristics* are also influenced by switching delays caused by the loading effect of the external power MOSFETs.

The switching frequency can also be adjusted to a value other than the preset frequencies by adding a resistor voltage-divider at HSD. See the *Adjusting the Switching Frequency* section.

#### *VTTR Reference (MAX8553 Only)*

The MAX8553's VTTR output is capable of sourcing or sinking up to 25mA of current. The VTTR output voltage is one-half of the voltage applied to REFIN. Bypass VTTR with at least a 1µF ceramic capacitor.

#### *Voltage Reference*

The voltage at REF is nominally 2.00V. Connect a 0.22µF ceramic bypass capacitor between REF and GND.

#### *EN and HSD (MAX8554 Only)*

EN is a logic input used to enable or shut down the MAX8554. Drive EN high or connect to V+ to enable the output. Drive EN low to place the MAX8554 in lowpower shutdown mode, reducing input current to less than 5µA (typ).

HSD senses the input voltage at the drain of the high-side MOSFET, which is used to set the high-side MOSFET ontime. For normal operation, connect HSD to the drain of the high-side MOSFET.

#### *EN/HSD Function (MAX8553 Only)*

In order to reduce pin count and package size, the MAX8553 features a dual-function input pin, EN/HSD. When EN/HSD is pulled to ground, the internal circuitry powers off, reducing current consumption to less than 5µA (typ). To enable normal operation, connect EN/HSD to the drain of the high-side MOSFET through a 5.1kΩ resistor (Figure 2). In this configuration, EN/HSD becomes an input that monitors the high-side MOSFET drain voltage (converter input voltage) and uses that measurement to calculate the appropriate on-time for the converter. If the enable function is not used, connect EN/HSD directly to the high-side MOSFET drain.

#### *Predischarge Mode*

The MAX8553/MAX8554 discharge the output to GND before the digital soft-start begins. When EN/HSD (EN) is pulled high, the MAX8553 (MAX8554) starts an internal counter, and forces  $V_{DL}$  to  $V_{VL}$ . This discharges the output to GND through the low-side MOSFET. If the output voltage is above ground before enable, the output voltage goes slightly negative due to energy stored in the output LC. If the load cannot tolerate a negative voltage, place a power Schottky diode from the output to PGND (anode to PGND) to act as a reverse-polarity clamp. The period for this discharge mode is 1.7ms. Both the buck controller and the VTTR buffer are turned off during this period. After the predischarge period, both the buck controller and the VTTR buffer are turned on and go through soft-start.

#### *Digital Soft-Start*

The digital soft-start allows a gradual increase of the internal current-limit level during startup to reduce the input surge current. The MAX8553/MAX8554 divide the soft-start period into five phases. During the first phase, the controller limits the current limit to only 20% of the full current limit. If the output does not reach the regulation within 425µs, soft-start enters the second phase and the current limit is increased by another 20%. This process repeats until the maximum current limit is reached (after 1.7ms) or when the output reaches the nominal regulation voltage, whichever occurs first. Adding a capacitor in parallel with the external ILIM resistor creates a continuously adjustable analog softstart function. If the foldback current-limiting feature is implemented in the application circuit, the maximum current limit is also a function of the output voltage and the resistors connected to ILIM.

#### *Power-Good Output (POK)*

POK is the open-drain output of the internal window comparators that continuously monitor VTT and VTTR for the MAX8553 and FB for the MAX8554. POK is actively held low in shutdown, and becomes high impedance when the outputs are within 12% of their respective nominal regulation voltage.

#### *Overvoltage Protection (OVP)*

When the buck output voltage rises above 120% of the nominal regulation voltage, the OVP circuit sets the fault latch, shuts down the PWM controller, and immediately pulls DH low and forces DL high. The negative current limit is also disabled. This turns on the low-side MOSFET, which rapidly discharges the output capacitors and clamps the output to ground. Note that immediately latching DL high can cause the output voltage to go slightly negative due to energy stored in the output LC at the instant the OVP occurs. If the load cannot tolerate a negative voltage, place a power Schottky diode from the output to PGND (anode to PGND) to act as a reverse-polarity clamp. Cycle EN or input power to reset the latch.

#### *Overcurrent Protection*

The current-limit circuit employs a unique "valley" current-sensing algorithm that uses the on-resistance of the low-side MOSFET as a current-sensing element. If the current-sense signal is above the current-limit threshold, the PWM is not allowed to initiate a new cycle. The actual peak current is greater than the current-limit threshold by an amount equal to the inductor ripple current (Figure 4). Therefore, the exact currentlimit characteristic and maximum load capability are a function of the MOSFET on-resistance, the inductor value, and the input voltage. The reward for this uncertainty is robust, lossless overcurrent sensing. There is also a negative current limit that prevents excessive reverse inductor currents when VOUT is sinking current. The negative current-limit threshold is set to approximately 110% of the positive current limit, and therefore tracks the positive current limit when ILIM is adjusted. The current-limit threshold can be adjusted with an external resistor (R<sub>ILIM</sub>) at ILIM. A precision 5µA pullup current source at ILIM sets a voltage drop on this resistor, adjusting the current-limit threshold from approximately 50mV to 200mV. In the adjustable mode, the current-limit threshold voltage is precisely 1/10 the voltage seen at ILIM. Therefore, choose RILIM equal to 2k $\Omega$ /mV of the current-limit threshold. The threshold defaults to 100mV when ILIM is connected to VL. The logic threshold for switchover to the 100mV default value is approximately V<sub>VL</sub> - 1V. The adjustable current limit can accommodate various MOSFETs. Alternately, foldback current limit can also be implemented by adding a resistor from ILIM to VOUT. See the *Setting the Current Limit* section.

*Figure 4. Inductor-Current Waveform*

Carefully observe the PC board layout guidelines to ensure that noise and DC errors do not corrupt the current-sense signals seen by LX and PGND. The IC must be mounted close to the low-side MOSFET with short, direct traces making a Kelvin-sense connection to the source and drain terminals. See the *PC Board Layout* section.

#### *Voltage Positioning*

The Quick-PWM control architecture responds virtually instantaneously to transient load changes and eliminates the control loop delay of conventional PWM controllers. Therefore, a large portion of the voltage deviation during a step load change is from the ESR (equivalent series resistance) of the output capacitors. For DDR termination applications, the maximum allowed voltage deviation is ±40mV for any output load transition from sourcing current to sinking current. Passive voltage positioning adjusts the converter's output voltage based on its load current to optimize transient response and minimize the required output capacitance.

Voltage positioning is implemented by connecting a low ohmic resistor (R4) as shown in Figure 2.

#### *MOSFET Drivers*

The DH and DL drivers are optimized to drive MOSFETs that can deliver up to 25A output current. An adaptive dead-time circuit monitors the DL output and prevents the high-side MOSFET from turning on until DL is fully off. There must be a low-resistance, lowinductance path from the DL driver to the MOSFET gate in order for the adaptive dead-time circuit to work properly. Otherwise, the sense circuitry in the MAX8553/ MAX8554 can interpret the MOSFET gate as "off" while there is actually still charge left on the gate. Use very short, wide traces measuring 10 squares to 20 squares (50 mils to 100 mils wide if the MOSFET is 1in from the MAX8553/MAX8554). This adaptive dead-time delay is in addition to a fixed delay of 30ns (typ). The dead time at the other edge (DH turning off) is determined by a fixed 32ns (typ) internal delay.

#### *Design Procedure*

#### *Setting the Output Voltage*

For the MAX8553, the output voltage,  $VVTT$ , is always 50% of VREFIN.

For the MAX8554, the output voltage can be adjusted from 600mV to 3.5V using a resistive voltage-divider (R2 and R3 in Figures 1 and 3). To set the voltage, choose a value for R3 in the range of  $1k\Omega$  to  $10k\Omega$ , then solve for R2 using the following equation:

$$
R2 = R3 \left( \frac{V_{OUT}}{V_{FB}} - 1 \right)
$$

where V<sub>FB</sub> is 0.6V.

#### *Inductor Selection*

Three key inductor parameters must be specified: inductance value (L), peak inductor current (IPEAK), and DC resistance (RDC). A good compromise between size and efficiency is to set the inductor peakto-peak ripple current equal to 30% of the maximum load current, thus  $LIR = 0.3$ . The switching frequency, input voltage, output voltage, and selected LIR determine the inductor value as follows:

$$
L = \frac{V_{OUT}(V_{IN} - V_{OUT})}{V_{IN} \times f_S \times I_{LOAD(MAX)} \times LIR}
$$

where fs is the switching frequency. The exact inductor value is not critical and can be adjusted in order to make trade-offs among size, cost, and efficiency. Lower inductor values minimize size and cost and also improve transient response but reduce efficiency and increase output voltage ripple due to higher peak currents. Higher inductance increases efficiency by reducing the RMS current.

Find a low-loss inductor with the lowest possible DC resistance that fits in the allotted dimensions. The inductor's current saturation rating must exceed the

peak inductor current at the maximum-defined load current (ILOAD(MAX)):

$$
I_{PEAK} = I_{LOAD(MAX)} + \left(\frac{LIR}{2}\right) \times I_{LOAD(MAX)}
$$

#### *Output-Capacitor Selection*

The key selection parameters for the output capacitor are the actual capacitance value, the ESR, the equivalent series inductance (ESL), and the voltage-rating requirements, which affect the overall stability, output ripple voltage, and transient response.

The worst-case output ripple has three components: variations in the charge stored in the output capacitor, the voltage drop across the capacitor's ESR, and ESL caused by the current into and out of the capacitor. This can be approximated by:

$$
V_{RIPPLE} = V_{RIPPLE(ESR)} + V_{RIPPLE(C)} + V_{RIPPLE(ESL)}
$$

The output voltage ripple due to the ESR is:

 $V_{\text{RIPPLE(ESR)}} = I_{\text{P-P}} \times \text{ESR}$ 

The output voltage ripple due to the output capacitance is:

$$
V_{\text{RIPPLE}(C)} = \frac{I_{\text{P-P}}}{8 \times C_{\text{OUT}} \times f_{\text{S}}}
$$

The output voltage ripple due to the ESL of the output capacitor is:

 $V$ RIPPLE (ESL) =  $(V_{IN} \times ESL) / (L+ESL)$ 

IP-P is the peak-to-peak inductor current:

$$
I_{\text{P-P}} = \frac{V_{\text{IN}} - V_{\text{OUT}}}{f_S \times L} \times \frac{V_{\text{OUT}}}{V_{\text{IN}}}
$$

After a load transient, the output voltage instantly changes by ESR x  $\Delta I$ <sub>LOAD</sub> + ESL x di/dt and the controllers respond within 100ns and try to regulate back to the nominal output value.

Solid polymer or OSCON electrolytic capacitors are recommended due to their low ESR and ESL at the switching frequency. Higher output-current applications require multiple output capacitors connected in parallel to meet the output ripple-voltage requirements. Do not exceed the capacitor's voltage or ripple-current ratings.

#### **MAXIM**

#### *Output-Capacitor Stability Consideration*

Stability is determined by the value of the ESR zero relative to the switching frequency. To ensure stability, the following condition must be met:

$$
f_{ESR} < \frac{f_S}{\pi}
$$

where fs is the switching frequency and:

$$
f_{ESR} = \frac{1}{2\pi \times R_{ESR} \times C_{OUT}}
$$

For a typical 300kHz application, the ESR zero frequency must be well below 95kHz, preferably below 50kHz. Do not put high-value ceramic capacitors directly across the feedback sense point without taking precautions to ensure stability. Large ceramic capacitors can have a high-ESR zero frequency and cause erratic, unstable operation. However, it is easy to add enough series resistance by placing the capacitors a couple of inches downstream from the feedback sense point, which should be as close as possible to the inductor.

The easiest method for checking stability is to apply a very fast zero-to-max load transient and carefully observe the output voltage-ripple envelope for overshoot and ringing. It can help to simultaneously monitor the inductor current with an AC current probe. Do not allow more than one cycle of ringing after the initial step-response under- or overshoot.

#### *Input-Capacitor Selection*

The input capacitor  $(C_{\text{IN}})$  reduces the current peaks drawn from the input supply and reduces noise injection. The source impedance to the input supply largely determines the value of  $C_{IN}$ . High source impedance requires high input capacitance. The input capacitor must meet the ripple current requirement (IRMS) imposed by the switching currents. The RMS input ripple current is given by:

$$
I_{RMS} = I_{LOAD} \times \frac{\sqrt{V_{OUT} \times (V_{IN} - V_{OUT})}}{V_{IN}}
$$

IRMS has a maximum value of 1/2 ILOAD, which occurs when V<sub>IN</sub> is twice VOUT.

For optimal circuit reliability, choose a capacitor that has less than 10°C temperature rise at the peak ripple current.

# **MAX8553/MAX8554** *MAX8553/MAX8554*

# *4.5V to 28V Input, Synchronous PWM Buck Controllers for DDR Termination and Point-of-Load Applications*

#### *Setting the Current Limit Constant Current Limit*

The adjustable current limit accommodates MOSFETs with a wide range of on-resistance values. The currentlimit threshold is adjusted with an external resistor connected from ILIM to GND (RILIM\_). The adjustment range is 50mV to 200mV measured across the low-side MOSFET. The value of RILIM is calculated using the following formula:

$$
R_{ILIM} = 10 \times \frac{I_{VALLEY}}{5 \mu A} \times R_{DS(ON)}
$$

where  $I_{\text{VAL}}$  is the valley current limit and  $R_{\text{DS}}(ON)$  is the on-resistance of the low-side MOSFET. To avoid reaching the current at a lower current than expected, use the maximum value for RDS(ON) at elevated junction temperature. Refer to the MOSFET manufacturer's data sheet for maximum values.

#### *Foldback Current Limit*

Foldback current limit is used to reduce power dissipation during overload and short-circuit conditions. This is accomplished by lowering the current-limit threshold as the output voltage drops due to the overload.

To use foldback current limit, connect a resistor (RFOBK) from ILIM to the output, and connect a resistor  $(R<sub>ILIM</sub>)$  from ILIM to GND (Figure 5). The values of  $R<sub>ILIM</sub>$ and RFOBK are calculated as follows:

First, select the percentage of foldback, PFB. This percent corresponds to the current limit when  $V_{\Omega U}$  equals zero divided by the current limit when  $V_{\text{OUT}}$  equals its nominal voltage. Typical values range from 15% to 30%. To solve for the resistor values, use the following equations:

$$
R_{FOBK} = \frac{P_{FB} \times V_{OUT}}{5 \mu A (1 - P_{FB})}
$$

$$
R_{ILIM} = \frac{10 \times R_{DS(ON)} \times I_{VALLEY} \times (1-P_{FB}) \times R_{FOBK}}{V_{OUT} - (10 \times R_{DS(ON)} \times I_{VALLEY} \times (1-P_{FB}))}
$$

If R<sub>ILIM</sub> results in a negative number, select another lowside MOSFET with lower R<sub>DS(ON)</sub> or increase PFB or a combination of both for the best compromise of cost, efficiency, and lower short-circuit power dissipation.

*Figure 5. Setting the Foldback Current Limit with Two Resistors, RILIM and RFOBK*

#### *Adjusting the Switching Frequency*

The switching frequency of the MAX8553/MAX8554 can be lowered from the value set by FSEL by adding a resistor voltage-divider to EN/HSD (HSD) as shown in Figure 6. This voltage-divider lowers the voltage the IC measures on EN/HSD (HSD), which increases the ontime. The switching frequency with the added resistordivider is calculated as follows:

$$
f_S \cong \frac{1}{K \times N} \times \frac{R2}{R1 + R2}
$$

where  $K = 1.7\mu s$  and N is given in Tables 1 and 2. To set the frequency, select a value for R2 between 10kΩ and 100kΩ, then calculate R1 from the following equation:

$$
R1 = \frac{1}{K \times N} \times \frac{R2}{f_S} - R2
$$

With the minimum input voltage, make sure that the voltage present at EN/HSD (HSD) is greater than 1.5V when the resistor-divider is used:

$$
\frac{V_{IN(MIN)} \times R2}{R1 + R2} > 1.5V
$$

#### *Setting Voltage Positioning*

The droop resistor, R<sub>DRP</sub> (R4) in Figure 2, in series with the output inductor before the output capacitor, sets the droop voltage, VDRP. Choose RDRP such that the output voltage at the maximum load current, including ripple, is just above the lower limit of the output tolerance:

$$
R_{DRP} < \frac{V_{OUT(TYP)} - V_{OUT(MIN)} - V_{RIPPLE} / 2}{V_{OUT(MAX)}}
$$

R<sub>DRP</sub> introduces some power dissipation, which is given by:

$$
P_{D(DRP)} = P_{DRP} \times (I_{OUT(MAX)})^2
$$

RDRP should be chosen to handle this power dissipation.

#### *Power MOSFET Selection*

The MAX8553/MAX8554 drive external, logic-level, Nchannel MOSFETs as the circuit-switch elements. The key selection parameters are:

**On-resistance (RDS(ON)):** The lower, the better.

**Maximum drain-to-source voltage (Vpss):** This should be at least 20% higher than the input supply rail at the high-side MOSFET's drain.

**Gate charges (QG, QGD, QGS):** The lower, the better.

*Figure 6. A resistor-divider (R1 and R2) is used to lower the switching frequency.*

*MAXM* 

Choose the MOSFETs with rated  $R_{DS(ON)}$  at  $V_{GS} = 4.5V$ . For a good compromise between efficiency and cost, choose the high-side MOSFET that has a conduction loss equal to switching loss at nominal input voltage and maximum output current (see below). For the low-side MOSFET, make sure that it does not spuriously turn on because of the dV/dt caused by the high-side MOSFET turning on, as this would result in shoot-through current degrading the efficiency. MOSFETs with a lower QGD to QGS ratio have higher immunity to dV/dt.

For proper thermal-management design, calculate the power dissipation at the desired maximum operating junction temperature, maximum output current, and worst-case input voltage (for low-side MOSFET, worst case is at VIN(MAX); for high-side MOSFET, it could be either at VIN(MIN) or VIN(MAX)). The high-side MOSFET and low-side MOSFET have different loss components due to the circuit operation. The low-side MOSFET operates as a zero voltage switch; therefore, major losses are: the channel conduction loss (PLSCC), the body-diode conduction loss (PLSDC), and the gatedrive loss (PLSDR):

$$
P_{\text{LSCC}} = \left(1 - \frac{V_{\text{OUT}}}{V_{\text{IN}}}\right) \times \left(I_{\text{LOAD}}\right)^2 \times P_{\text{DS}(\text{ON})}
$$

Use RDS(ON) at TJ(MAX):

$$
P_{\text{LSDC}} = 2 \times I_{\text{LOAD}} \times V_{F} \times t_{\text{DT}} \times t_{S}
$$

where  $V_F$  is the body-diode forward-voltage drop, t $DT$  is the dead time  $(-30ns)$ , and fs is the switching frequency.

Because of the zero-voltage switch operation, low-side MOSFET gate-drive loss occurs as a result of charging and discharging the input capacitance (C<sub>ISS</sub>). This loss is distributed among the average DL gate driver's pullup and pulldown resistance, R<sub>DL</sub> (~1.2Ω), and the internal gate resistance (R<sub>GATE</sub>) of the MOSFET (~2Ω). The drive power dissipated is given by:

$$
P_{LSDR} = C_{ISS} \times (V_{GS})^2 \times f_S \times \frac{R_{GATE}}{R_{GATE} + R_{DL}}
$$

The high-side MOSFET operates as a duty-cycle control switch and has the following major losses: the channel conduction loss (PHSCC), the VI overlapping switching loss (PHSSW), and the drive loss (PHSDR). The high-side MOSFET does not have body-diode conduction loss because the diode never conducts current.

$$
P_{HSCC} = \frac{V_{OUT}}{V_{IN}} \times (I_{LOAD})^2 \times R_{DS(ON)}
$$

Use RDS(ON) at TJ(MAX):

$$
P_{HSSW} = V_{IN} \times I_{LOAD} \times f_S \times \frac{Q_{GS} + Q_{GD}}{I_{GATE}}
$$

where I<sub>GATE</sub> is the average DH driver output current determined by:

$$
I_{\text{GATE}} = \frac{2.5V}{R_{\text{DH}} + R_{\text{GATE}}}
$$

where R<sub>DH</sub> is the high-side MOSFET driver's on-resistance (1.4Ω typ) and RGATE is the internal gate resistance of the MOSFET  $(-2Ω)$ :

$$
P_{HSDR} = Q_G \times V_{GS} \times f_S \times \frac{R_{GATE}}{R_{GATE} + R_{DH}}
$$

where  $VGS = VVL = 5V$ .

When the MAX8553 is sinking current, the high-side MOSFET operates as a zero-voltage switch and the low-side MOSFETs operate as a nonzero-voltage switch.

In addition to the losses above, allow about 20% more for additional losses due to MOSFET output capacitances and low-side MOSFET body-diode reverse recovery charge dissipated in the high-side MOSFET that is not well defined in the MOSFET data sheet. Refer to the MOSFET data sheet for thermal-resistance specifications to calculate the PC board area needed to maintain the desired maximum operating junction temperature with the above calculated power dissipations.

To reduce EMI caused by switching noise, add a 0.1µF ceramic capacitor from the high-side switch drain to the low-side switch source, or add resistors in series with DH and DL to slow down the switching transitions. Adding series resistors increases the power dissipation of the MOSFET, so ensure that this does not overheat the MOSFET.

#### *Control IC Power Dissipation*

Power dissipation in the MAX8553/MAX8554 IC is primarily due to the on-chip MOSFETs' gate drivers (DH and DL). This power dissipation depends on the gate charge of the external MOSFETs used. Power dissipation in the MAX8553 also depends on the VTTR load current (IVTTR). Use the following equation to calculate the power dissipation:

$$
P_D = (V_{V+}) \times [f_S \times (Q_{GH} + Q_{GL}) + I_{VTTR}]
$$

where Q<sub>GH</sub> and Q<sub>GL</sub> are the total gate charge of the high-side and low-side MOSFETs, respectively. Select the switching frequency and  $V_{V+}$  correctly to ensure the power dissipation does not exceed the package power-dissipation requirement.

#### *Applications Information*

#### *PC Board Layout*

A properly designed PC board layout is important in any switching regulator. The switching power stage requires particular attention. If possible, mount all the power components on the top-side of the board with their ground terminals flush against one another. Follow these guidelines for good PC board layout:

- 1) Keep the high-current paths short, especially at the ground terminals. This practice is essential for stable, low-jitter operation.
- 2) Connect GND and PGND together at a single point.
- 3) Keep the power traces and load connections short. This practice is essential for high efficiency. The use of thick copper PC boards (2oz vs. 1oz) can noticeably enhance full-load efficiency. Correctly routing PC board traces is a difficult task that must be approached in terms of fractions of centimeters, where a single mΩ of excess trace resistance causes a measurable efficiency penalty.
- 4) LX and PGND connections to the low-side MOSFET for current limiting must be made using Kelvinsense connections in order to guarantee the current-limit accuracy. With 8-pin SO MOSFETs, this can be done by routing power to the MOSFETs from

# *MAX8553/MAX8554* MAX8553/MAX8554

# *4.5V to 28V Input, Synchronous PWM Buck Controllers for DDR Termination and Point-of-Load Applications*

outside using the top copper layer, while tying in PGND and LX inside (underneath) the 8-pin SO package.

- 5) When trade-offs in trace lengths must be made, it is preferable to allow the inductor charging path to be made longer than the discharge path. For example, it is better to allow some extra distance between the input capacitors and the high-side MOSFET than to allow distance between the inductor and the lowside MOSFET or between the inductor and the output filter capacitor.
- 6) It may be desirable to deliberately introduce some trace length (droop resistance) between the FB inductor node and the output filter capacitor to meet the stability criteria ( $f_{ESR} < f_S / \pi$ ).
- 7) Place feedback resistors as close as possible to the IC.
- 8) Route high-speed switching nodes away from sensitive analog nodes.
- 9) Make all pin-strap control input connections (ILIM, etc.) to GND or VL close to the chip, and do not connect to PGND.
